## **Categories of Learning**

Learning

#### Unsupervised Learning

clustering, density estimation

#### Supervised Learning

learning from a training data set, inference on the test data

#### Reinforcement Learning

no supervision, but a reward function

# Discriminant Function

no prob. formulation, learns a function from objects  $\mathcal X$  to labels  $\mathcal Y$ .

# Discriminative Model

estimates the

posterior  $p(y_k \mid \mathbf{x})$  for each class

# **Generative Model**

est. the likelihoods

 $p(\mathbf{x} \mid y_k)$  and use Bayes rule for the post.

## **Mathematical Formulation (Rep.)**

Suppose we are given a set  $\mathcal{X}$  of objects and a set  $\mathcal{Y}$  of object categories (classes). In the learning task we search for a mapping  $\varphi: \mathcal{X} \to \mathcal{Y}$  such that *similar* elements in  $\mathcal{X}$  are mapped to *similar* elements in  $\mathcal{Y}$ .

#### Difference between regression and classification:

- In regression,  ${\mathcal Y}$  is **continuous**, in classification it is discrete
- Regression learns a function, classification usually learns class labels

For now we will treat regression

#### **Basis Functions**

In principal, the elements of  $\mathcal{X}$  can be anything (e.g. real numbers, graphs, 3D objects). To be able to treat these objects mathematically we need functions  $\phi$  that map from  $\mathcal{X}$  to  $\mathbb{R}^N$ . We call these the basis functions.

We can also interpret the basis functions as functions that extract features from the input data.

Features reflect the properties of the objects (width, height, etc.).

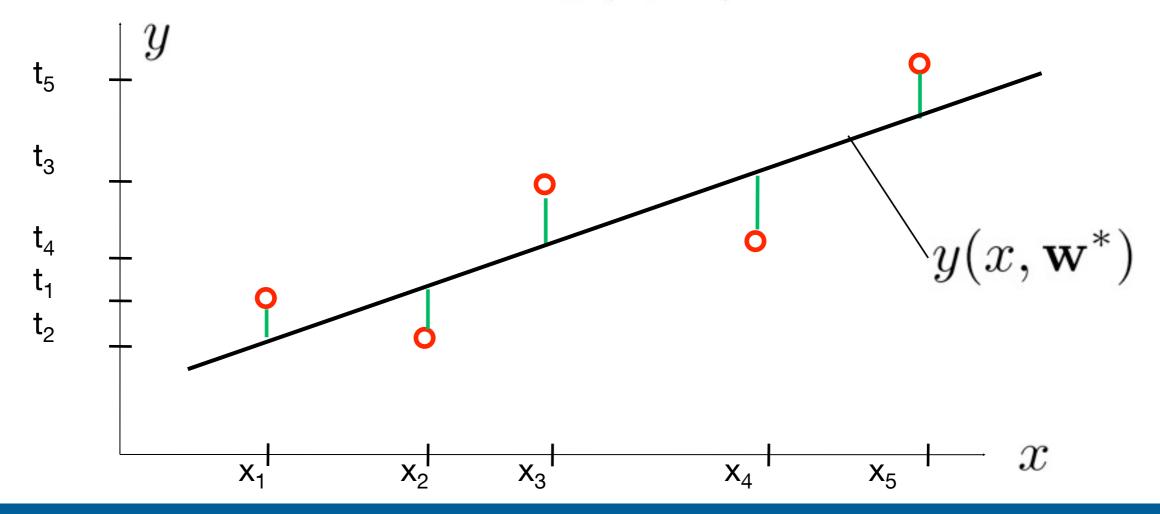

Dr. Rudolph Triebel

Computer Vision Group

## Simple Example: Linear Regression

- Assume:  $\mathcal{X}=\mathbb{R},\ \mathcal{Y}=\mathbb{R},\ \phi=I$  (identity)
- Given: data points  $(x_1, t_1), (x_2, t_2), ...$
- Goal: predict the value t of a new example x
- Parametric formulation:  $y(x, \mathbf{w}) = w_0 + w_1 x$

## **Linear Regression**

To evaluate the function y, we need an error function:

$$E(\mathbf{w}) = \frac{1}{2} \sum_{i=1}^{N} \left( y(x_i, \mathbf{w}) - t_i \right)^2$$
 Squared Errors"

We search for parameters  $\mathbf{w}^*$  s.th.  $E(\mathbf{w}^*)$  is minimal:

$$\nabla E(\mathbf{w}) = \sum_{i=1}^{N} (y(x_i, \mathbf{w}) - t_i) \nabla y(x_i, \mathbf{w}) \doteq (0 \quad 0)$$

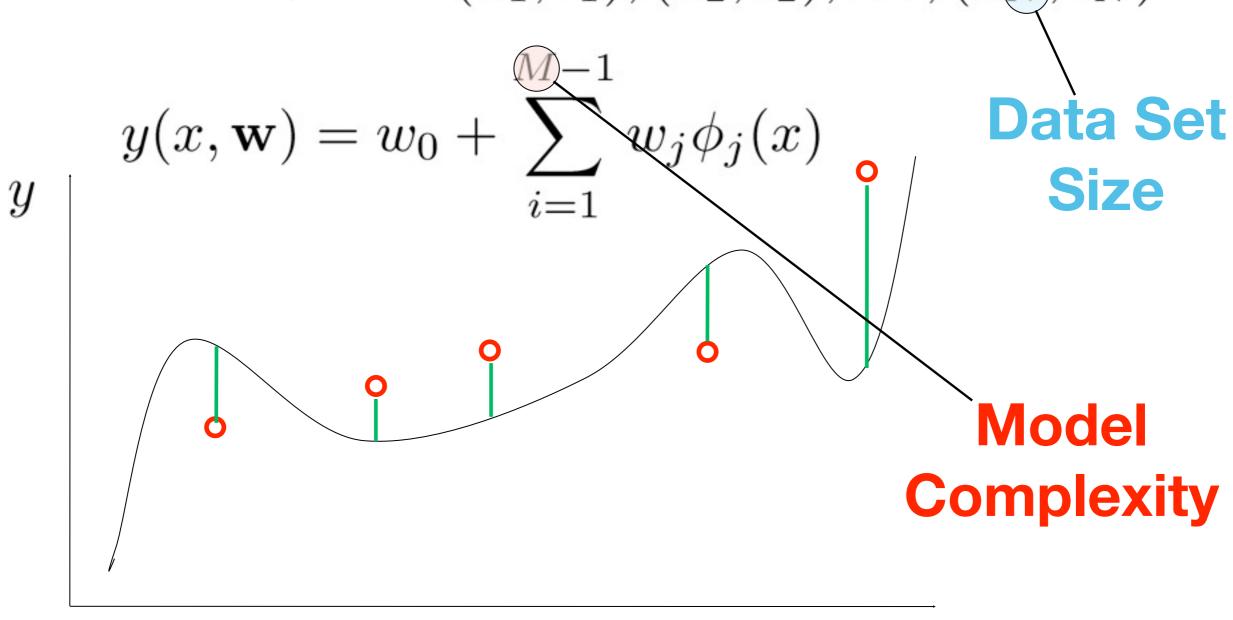

$$y(x_i, \mathbf{w}) = w_0 + w_1 x_i \qquad \Rightarrow \qquad \nabla y(x_i, \mathbf{w}) = (1 \quad x_i)$$

Using vector notation:  $\mathbf{x}_i := (1 \quad x_i)^T \quad y(x_i, \mathbf{w}) = \mathbf{w}^T \mathbf{x}_i$ 

$$\nabla E(\mathbf{w}) = \sum_{i=1}^{N} \mathbf{w}^{T} \mathbf{x}_{i} \mathbf{x}_{i}^{T} - \sum_{i=1}^{N} t_{i} \mathbf{x}_{i}^{T} = (0 \quad 0) \Rightarrow \mathbf{w}^{T} \underbrace{\sum_{i=1}^{N} \mathbf{x}_{i} \mathbf{x}_{i}^{T}}_{=:A^{T}} = \underbrace{\sum_{i=1}^{N} t_{i} \mathbf{x}_{i}^{T}}_{=:b^{T}}$$

Now we have:  $\mathcal{X} = \mathbb{R}, \ \mathcal{Y} = \mathbb{R}, \ \phi_j(x) = x^j$ 

Given: data points  $(x_1,t_1),(x_2,t_2),\ldots,(x_N,t_N)$ 

x

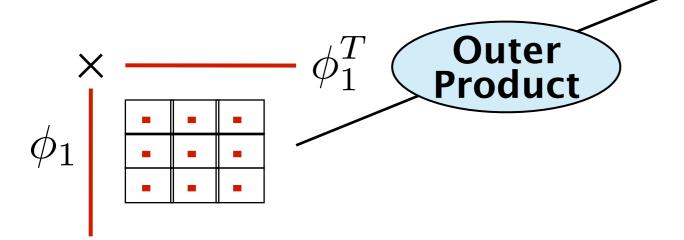

We define:  $\phi(x) := (1, \phi_1(x), \dots, \phi_{M-1}(x))$  "Basis functions"

And obtain:

$$y(x, \mathbf{w}) = \mathbf{w}^T \boldsymbol{\phi}(x)$$

$$E(\mathbf{w}) = \frac{1}{2} \sum_{i=1}^{N} (\mathbf{w}^{T} \phi(x_i) - t_i)^2$$

$$\nabla E(\mathbf{w}) = \mathbf{w}^T \left( \sum_{i=1}^N \phi(x_i) \phi(x_i)^T \right) - \sum_{i=1}^N t_i \phi(x_i)^T$$

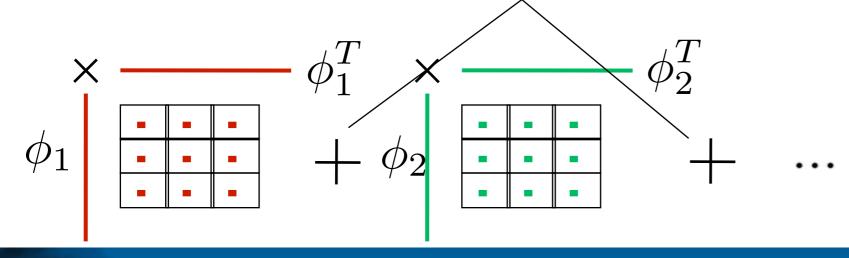

We define: 
$$\phi(x) := (1, \phi_1(x), \dots, \phi_{M-1}(x))$$

And obtain:

$$y(x, \mathbf{w}) = \mathbf{w}^T \boldsymbol{\phi}(x)$$

$$E(\mathbf{w}) = \frac{1}{2} \sum_{i=1}^{N} (\mathbf{w}^{T} \phi(x_i) - t_i)^2$$

$$\nabla E(\mathbf{w}) = \mathbf{w}^T \left( \sum_{i=1}^N \phi(x_i) \phi(x_i)^T \right) - \sum_{i=1}^N t_i \phi(x_i)^T$$

Dr. Rudolph Triebel

Computer Vision Group

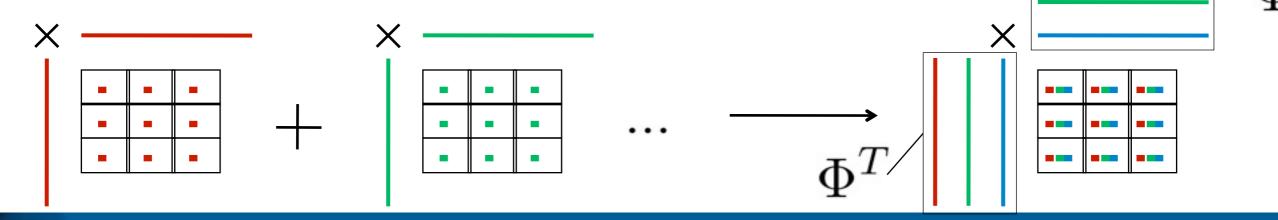

We define:  $\phi(x) := (1, \phi_1(x), \dots, \phi_{M-1}(x))$ 

And obtain:

$$y(x, \mathbf{w}) = \mathbf{w}^T \boldsymbol{\phi}(x)$$

$$E(\mathbf{w}) = \frac{1}{2} \sum_{i=1}^{N} (\mathbf{w}^{T} \phi(x_i) - t_i)^2$$

$$\nabla E(\mathbf{w}) = \mathbf{w}^T \left( \sum_{i=1}^N \phi(x_i) \phi(x_i)^T \right) - \sum_{i=1}^N t_i \phi(x_i)^T$$

Thus, we have: 
$$\sum_{i=1}^N oldsymbol{\phi}(x_i) oldsymbol{\phi}(x_i)^T = \Phi^T \Phi$$

Thus, we have: 
$$\sum_{i=1}^{N} \phi(x_i) \phi(x_i)^T = \Phi^T \Phi$$
 where 
$$\Phi = \begin{pmatrix} \phi_0(x_1) & \phi_1(x_1) & \dots & \phi_{M-1}(x_1) \\ \phi_0(x_2) & \phi_1(x_2) & \dots & \phi_{M-1}(x_2) \\ \vdots & \vdots & \ddots & \vdots \\ \phi_0(x_N) & \phi_1(x_N) & \dots & \phi_{M-1}(x_N) \end{pmatrix}$$

$$\nabla E(\mathbf{w}) = \mathbf{w}^T \Phi^T \Phi - \mathbf{t}^T \Phi \qquad \Rightarrow \qquad \Phi^T \Phi \mathbf{w} = \Phi^T \mathbf{t}$$

It follows: 
$$\mathbf{w} = (\Phi^T \Phi)^{-1} \Phi^T \mathbf{t}$$
 "Pseudoinverse"  $\Phi^+$ 

## Computing the Pseudoinverse

Mathematically, a pseudoinverse  $\Phi^+$  exists for every matrix  $\Phi$ .

However: If  $\Phi$  is (close to) singular the direct solution of  $\Phi$  is numerically unstable.

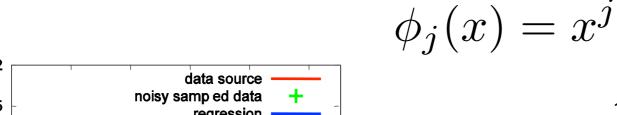

Therefore: Singular Value Decomposition (SVD) is used:  $\Phi = UDV^T$  where

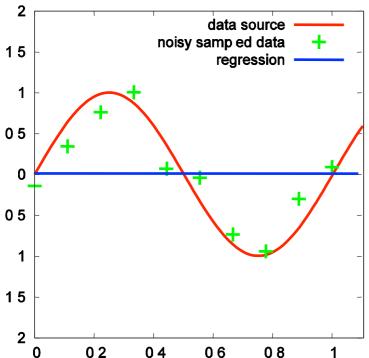

- ullet matrices U and V are orthogonal matrices
- $\bullet$  *D* is a diagonal matrix

Then:  $\Phi^+ = VD^+U^T$  where  $D^+$  contains the *reciprocal* of all non-zero elements of D

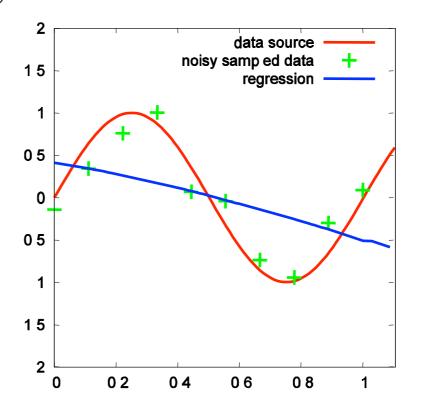

## A Simple Example

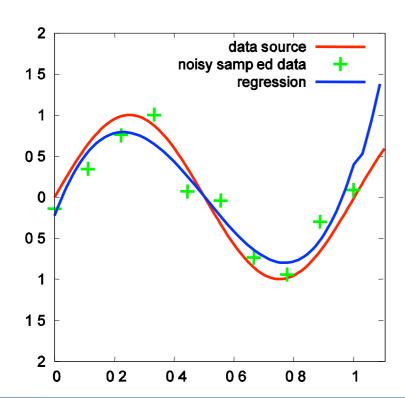

$$N = 10$$

$$M = 1$$

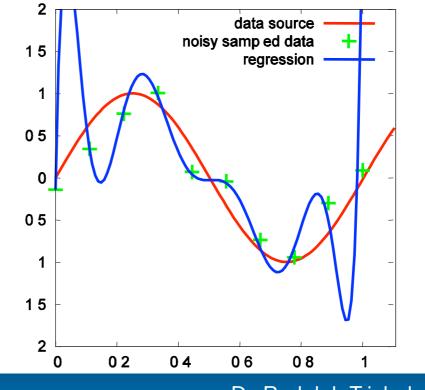

$$N = 10$$

$$M = 3$$

$$N = 10$$

$$M=5$$

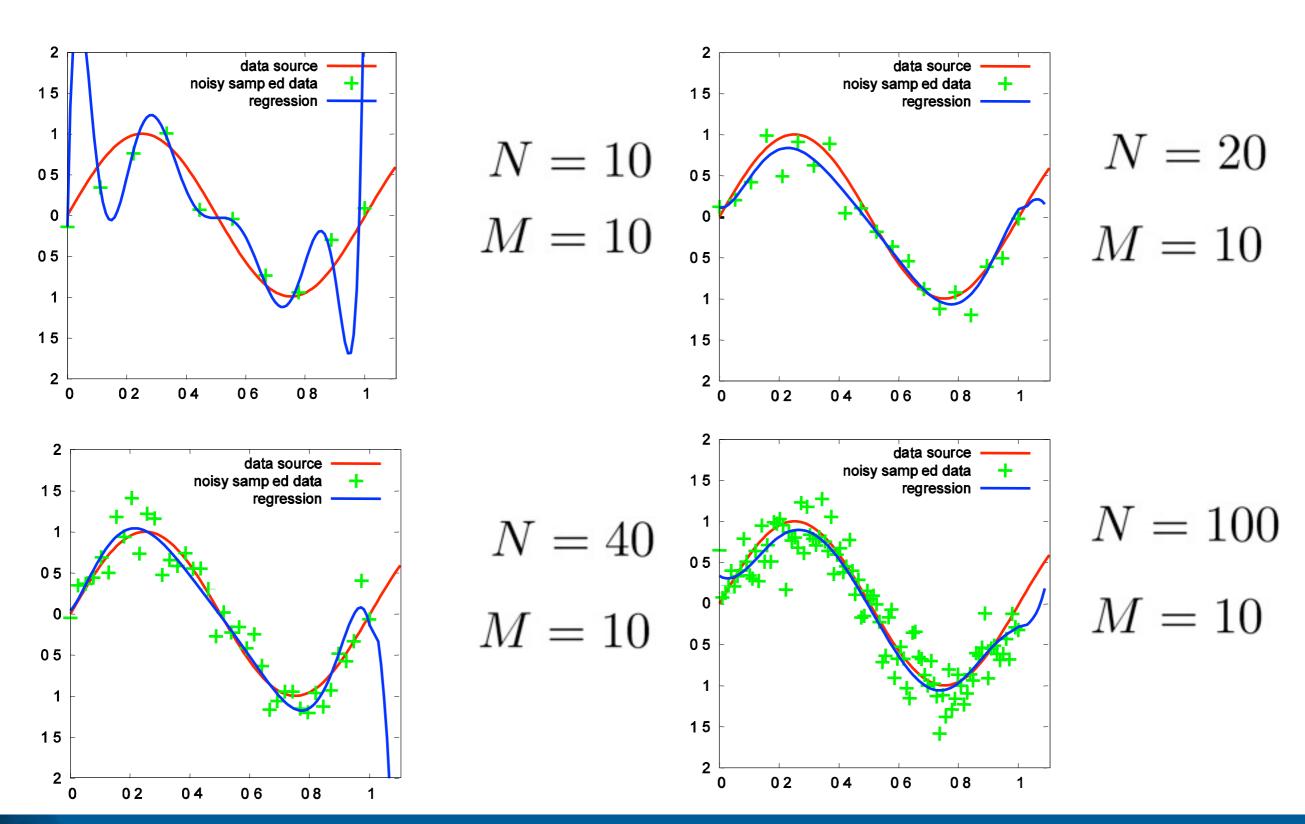

$$N = 10$$

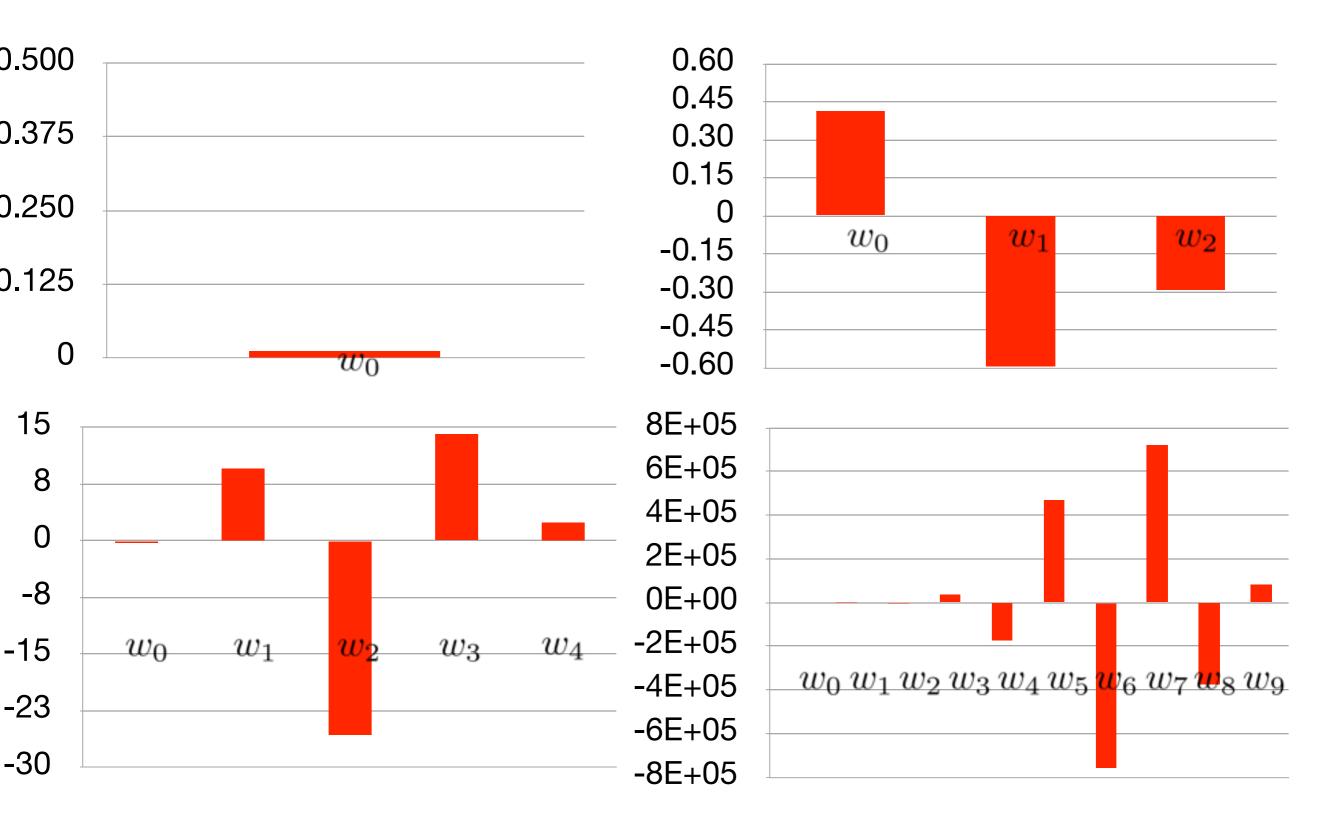

$$M = 10$$

## Varying the Sample Size

## The Resulting Model Parameters

#### **Other Basis Functions**

#### Other basis functions are possible:

Gaussian basis function:

$$\phi_j(x):=\exp\left(-rac{(x-\mu_j)^2}{2s^2}
ight) \;\; ext{where} \;\;\; egin{array}{c} \mu_j riangleq ext{mean val} \ s riangleq ext{scale} \end{array}$$
 Sigmoidal basis function:

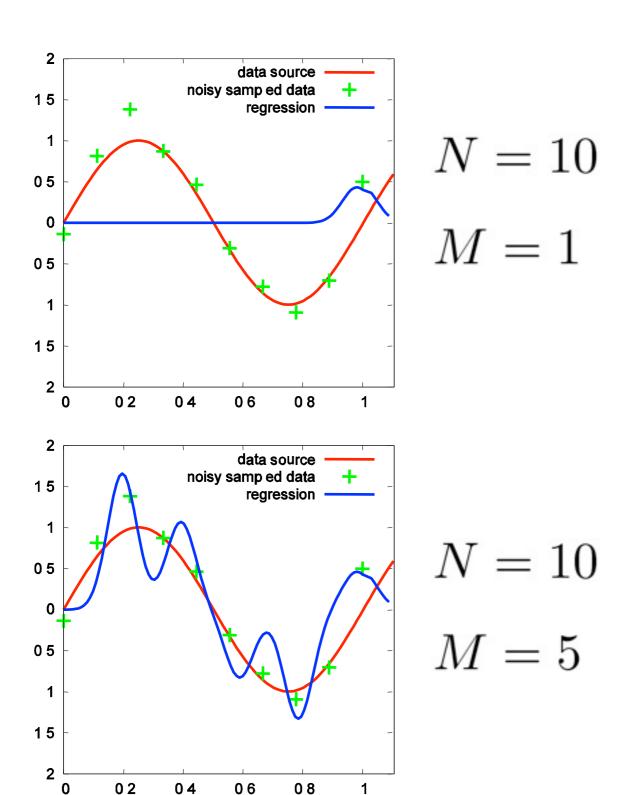

Sigmoidal basis function:

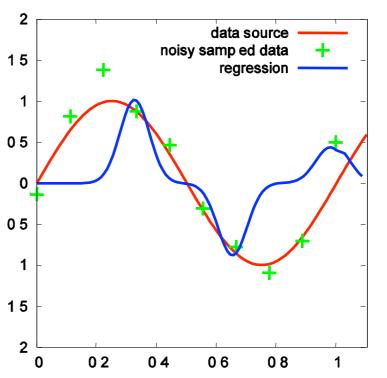

$$\phi_j(x) := \sigma\left(\frac{x-\mu_j}{s}\right) \text{ where } \qquad \sigma(a) = \frac{1}{1+\exp(-a)}$$

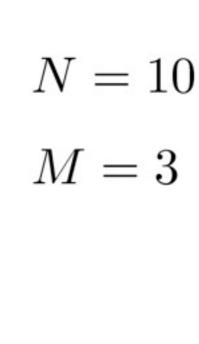

In both cases a set of mean values is required. These define the locations of the basis functions.

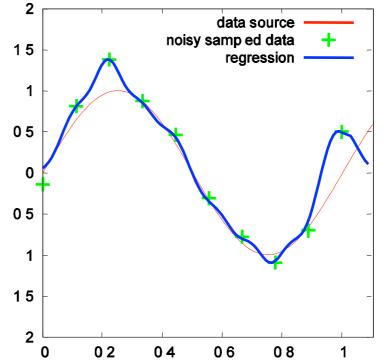

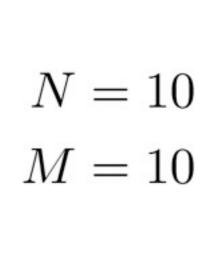

#### **Gaussian Basis Functions**

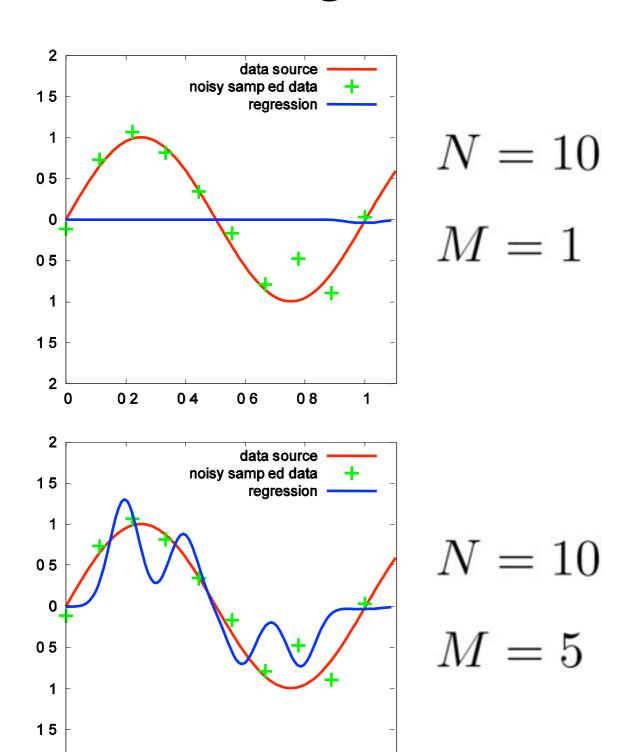

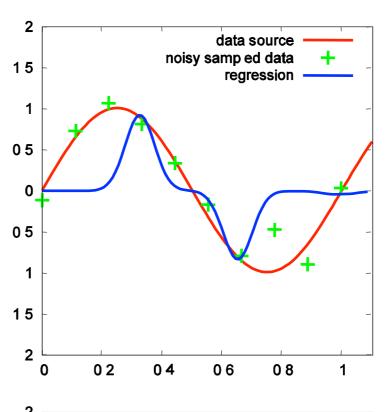

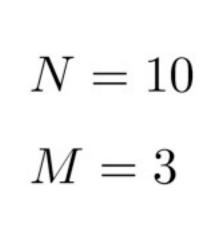

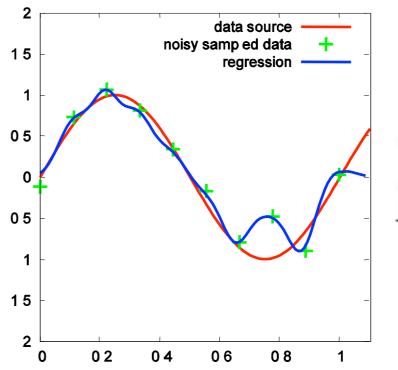

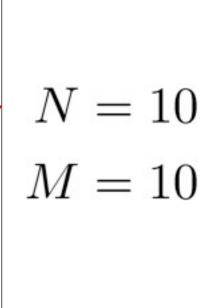

## **Sigmoidal Basis Functions**

#### **Observations**

- The higher the model complexity grows, the better is the fit to the data
- If the model complexity is too high, all data points are explained well, but the resulting model oscillates very much. It can not generalize well.
   This is called *overfitting*.
- By increasing the size of the data set (number of samples), we obtain a better fit of the model
- More complex models have larger parameters

**Problem:** How can we find a good model complexity for a given data set with a fixed size?

## Regularization

We observed that complex models yield large parameters, leading to oscillation. Idea:

Minimize the error function and the magnitude of the parameters simultaneously

We do this by adding a regularization term:

$$\tilde{E}(\mathbf{w}) = \frac{1}{2} \sum_{i=1}^{N} \left( \mathbf{w}^{T} \boldsymbol{\phi}(x) - t_{i} \right)^{2} + \frac{\lambda}{2} ||\mathbf{w}||^{2}$$

where  $\lambda$  rules the influence of the regularization.

## Regularization

As above, we set the derivative to zero:

$$\nabla \tilde{E}(\mathbf{w}) = \sum_{i=1}^{N} (\mathbf{w}^{T} \boldsymbol{\phi}(x) - t_i) \boldsymbol{\phi}(x)^{T} + \lambda \mathbf{w}^{T} \doteq \mathbf{0}^{T}$$

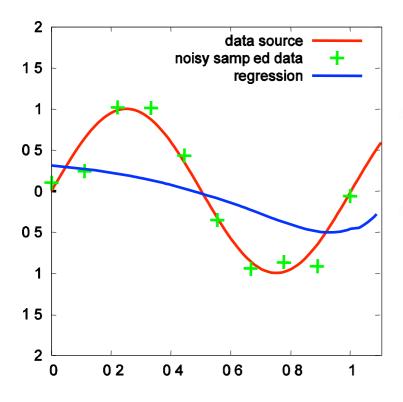

$$\mathbf{w}^T \Phi^T \Phi + \lambda \mathbf{w}^T = \mathbf{t}^T \Phi \quad \Rightarrow \quad (\lambda I + \Phi^T \Phi) \mathbf{w} = \Phi^T \mathbf{t}$$

$$\mathbf{w} = (\lambda I + \Phi^T \Phi)^{-1} \Phi^T \mathbf{t}$$

With regularization, we can find a complex model for a small data set. However, the problem now is to find an appropriate regularization coefficient  $\lambda$ .

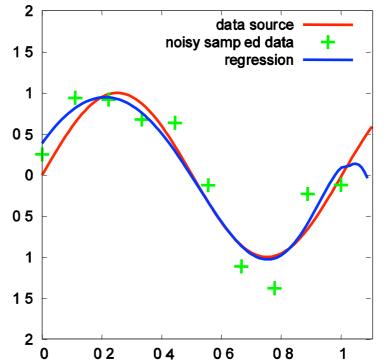

## Regularized Results

$$N = 10$$

$$M = 10$$

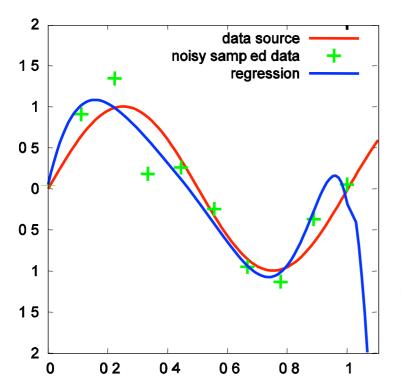

$$\lambda = 1$$

$$N = 10$$

$$M = 10$$

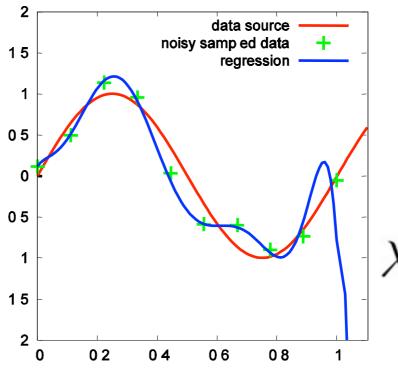

$$M = 10$$
$$\lambda = 10^{-3}$$

$$N = 10$$

$$M = 10$$

$$\lambda = 10^{-6}$$

$$N = 10$$

$$M = 10$$

$$\lambda = 10^{-11}$$

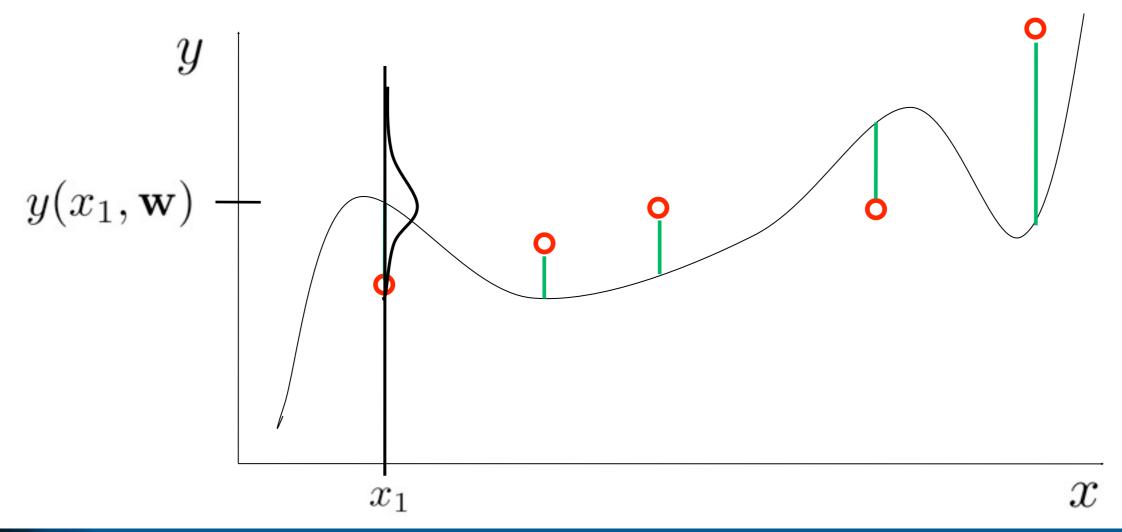

#### The Problem from a Different View

Assume that y is affected by Gaussian noise:

$$t = y(x, \mathbf{w}) + \epsilon$$
 where  $\epsilon \rightsquigarrow \mathcal{N}(.; 0, \sigma^2)$ 

Thus, we have  $p(t \mid x, \mathbf{w}, \sigma) = \mathcal{N}(t; y(x, \mathbf{w}), \sigma^2)$ 

**Aim:** we want to find the w that maximizes p.

 $p(t \mid x, \mathbf{w}, \sigma)$  is the *likelihood* of the measured data given a model. Intuitively:

Find parameters  $\mathbf{w}$  that maximize the probability of measuring the already measured data t.

## "Maximum Likelihood Estimation"

We can think of this as fitting a model w to the data t.

Note:  $\sigma$  is also part of the model and can be estimated. For now, we assume  $\sigma$  is known.

Given data points:  $(x_1, t_1), (x_2, t_2), \dots, (x_N, t_N)$ 

Assumption: points are drawn independently from *p*:

$$p(\mathbf{t} \mid \mathbf{x}, \mathbf{w}, \sigma) = \prod_{i=1}^{N} p(t_i \mid \mathbf{x}, \mathbf{w}, \sigma)$$
$$= \prod_{i=1}^{N} \mathcal{N}(t_i; \mathbf{w}^T \boldsymbol{\phi}(x_i), \sigma^2)$$

#### where:

$$\mathbf{x} = (x_1, x_2, \dots, x_N)$$

$$\mathbf{t} = (t_1, t_2, \dots, t_N)$$

Instead of maximizing *p* we can also maximize its

logarithm (monotonicity of the logarithm)

$$\ln p(\mathbf{t} \mid \mathbf{x}, \mathbf{w}, \sigma) = \sum_{i=1}^{N} \ln p(t_i \mid \mathbf{x}, \mathbf{w}, \sigma)$$

$$= \frac{1}{2} \sum_{i=1}^{N} -\ln(\sigma^2) - \ln(2\pi) - \frac{1}{\sigma^2} (\mathbf{w}^T \boldsymbol{\phi}(x_i) - t_i)^2$$

$$= \frac{-N(\ln(\sigma^2) + \ln(2\pi))}{2} \frac{1}{\sigma^2} \sum_{i=1}^{N} (\mathbf{w}^T \boldsymbol{\phi}(x_i) - t_i)^2$$

Constant for all w

Is equal to  $E(\mathbf{w})$ 

The parameters that maximize the likelihood are equal to the minimum of the sum of squared errors

$$\ln p(\mathbf{t} \mid \mathbf{x}, \mathbf{w}, \sigma) = \sum_{i=1}^{N} \ln p(t_i \mid \mathbf{x}, \mathbf{w}, \sigma)$$

$$= \frac{1}{2} \sum_{i=1}^{N} -\ln(\sigma^2) - \ln(2\pi) - \frac{1}{\sigma^2} (\mathbf{w}^T \boldsymbol{\phi}(x_i) - t_i)^2$$

$$= \frac{-N(\ln(\sigma^2) + \ln(2\pi))}{2} - \frac{1}{\sigma^2} \sum_{i=1}^{N} (\mathbf{w}^T \boldsymbol{\phi}(x_i) - t_i)^2$$

$$\mathbf{w}_{ML} := \arg \max_{\mathbf{w}} \ln p(\mathbf{t} \mid \mathbf{x}, \mathbf{w}, \sigma) = \arg \min_{\mathbf{w}} E(\mathbf{w}) = (\Phi^T \Phi)^{-1} \Phi^T \mathbf{t}$$

The ML solution is obtained using the Pseudoinverse

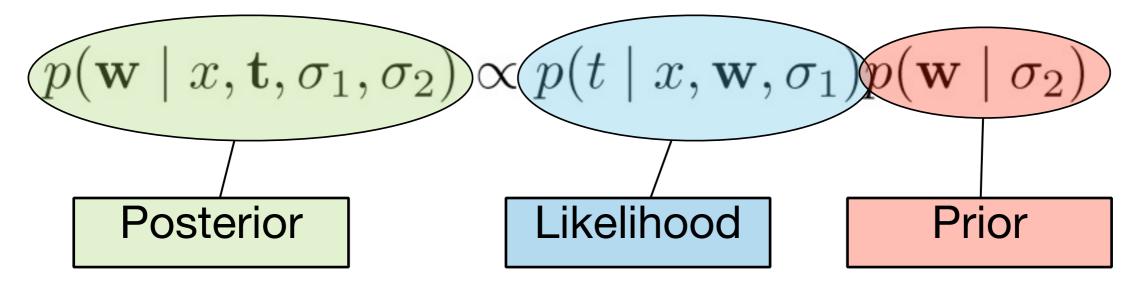

#### **Maximum A-Posteriori Estimation**

So far, we searched for parameters w, that maximize the data likelihood. Now, we assume a Gaussian *prior*:

$$p(\mathbf{w} \mid \sigma_2) = \mathcal{N}(\mathbf{w}; \mathbf{0}, \sigma_2 I)$$

Using this, we can compute the *posterior* (Bayes):

## "Maximum A-Posteriori Estimation (MAP)"

### **Maximum A-Posteriori Estimation**

So far, we searched for parameters w, that maximize the data likelihood. Now, we assume a Gaussian prior:

$$p(\mathbf{w} \mid \sigma_2) = \mathcal{N}(\mathbf{w}; \mathbf{0}, \sigma_2 I)$$

Using this, we can compute the posterior (Bayes):

$$p(\mathbf{w} \mid x, \mathbf{t}, \sigma_1, \sigma_2) \propto p(t \mid x, \mathbf{w}, \sigma_1) p(\mathbf{w} \mid \sigma_2)$$

strictly: 
$$p(\mathbf{w} \mid x, \mathbf{t}, \sigma_1, \sigma_2) = \frac{p(t \mid x, \mathbf{w}, \sigma_1)p(\mathbf{w} \mid \sigma_2)}{\int p(t \mid x, \mathbf{w}, \sigma_1)p(\mathbf{w} \mid \sigma_2)d\mathbf{w}}$$

but the denominator is independent of  $\mathbf{w}$  and we want to maximize p.

#### **Maximum A-Posteriori Estimation**

$$\ln p(\mathbf{w} \mid x, \mathbf{t}, \sigma_1, \sigma_2) \propto \ln p(t \mid x, \mathbf{w}, \sigma_1) + \ln p(\mathbf{w} \mid \sigma_2)$$

const. 
$$-\frac{1}{\sigma_1^2} \sum_{i=1}^N (\mathbf{w}^T \boldsymbol{\phi}(x) - t_i)^2$$

const. 
$$-\frac{1}{2\sigma_2^2}\mathbf{w}^T\mathbf{w}$$

$$\propto -\frac{1}{\sigma_1^2} \left( \sum_{i=1}^N (\mathbf{w}^T \boldsymbol{\phi}(x) - t_i)^2 + \frac{\sigma_1^2}{\sigma_2^2} \mathbf{w}^T \mathbf{w} \right)$$

This is equal to the regularized error minimization.

The MAP Estimate corresponds to a regularized error minimization where  $\lambda = (\sigma_1 / \sigma_2)^2$ 

## **Summary**

- Regression is a method to find a mathematical model (function) for a given data set
- Regression can be done by minimizing the sum of squared (SSE) errors, i.e. the distances to the data
- Maximum-likelihood estimation uses a probabilis-tic representation to fit a model into noisy data
- Maximum-likelihood under Gaussian noise is equivalent to SSE regression.
- Maximum-a-posteriori (MAP) estimation assumes a (Gaussian) prior on the model parameters
- MAP is solved by regularized regression

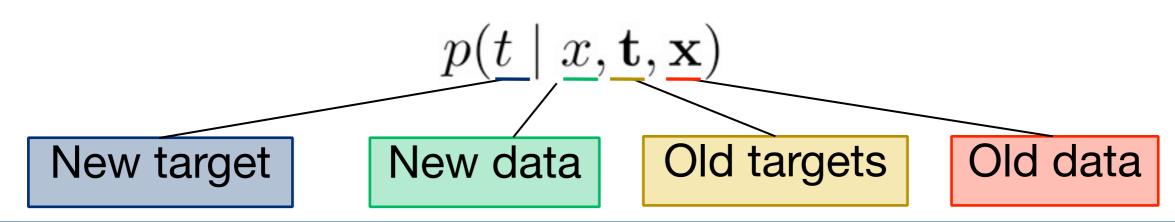

# **Bayesian Linear Regression**

## **Bayesian Linear Regression**

- Using MAP, we can find optimal model parameters, but for practical applications two questions arise:
- What happens in the case of sequential data, i.e. the data points are observed subsequently?
- Can we model the probability of measuring a new data point, given all old data points? This is called the predictive distribution:

## **Sequential Data**

- Given: Prior mean  $\mathbf{m}_0$  and covariance  $S_0$ , noise covariance  $\sigma$   $p_0(\mathbf{w} \mid S_0) = \mathcal{N}(\mathbf{w}; \mathbf{m}_0, S_0)$
- 1. Set i = 0
- 2. Observe data point  $(x_i, t_i)$
- 3. Formulate the likelihood  $p(t_i \mid x_i, \mathbf{w})$  as a function of  $\mathbf{w}$  (= Gaussian with mean  $\phi(x_i)^T \mathbf{w}$  and covariance  $\sigma$ )
- 4. Multiply the likelihood with the prior  $p_i(\mathbf{w} \mid S_i)$  and normalize (= Gaussian with  $\mathbf{m}_{i+1}$  and  $S_{i+1}$ )
- 5. This results in a new prior  $p_{i+1}(\mathbf{w} \mid S_{i+1})$
- 6. Go back to 1. if there are still data points available

## A Simple Example

Our aim to fit a straight line into a set of data points.

Assume we have:

Basis functions are equal to identity  $\phi(\mathbf{x}) = \mathbf{x}$ 

Prior mean is zero, prior covariance  $\sigma_2^2=0.5$ , noise variance is  $\sigma_1^2=0.2^2$ 

Ground truth is  $f(x, \mathbf{a}) = a_0 + a_1 x$  where  $a_1 = 0.5$ 

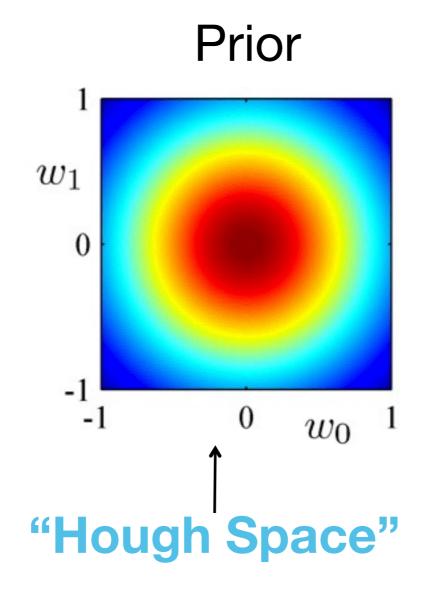

Data points are sampled from ground truth  $a_0 = -0.3$ 

#### Thus:

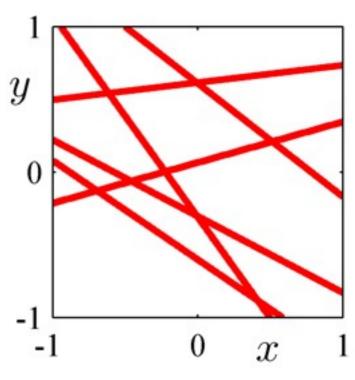

We want to recover  $a_0$  and  $a_1$  from the sequentially incoming data points  $(x_1, t_1), (x_2, t_2), \ldots$

#### **The Predictive Distribution**

We obtain the predictive distribution by integrating over all possible model parameters:

$$p(t\mid x,\mathbf{t},\mathbf{x}) = \int \underline{p(t\mid x,\mathbf{w})p(\mathbf{w}\mid \mathbf{x},\mathbf{t})}d\mathbf{w}$$
 New data likelihood Old data posterior

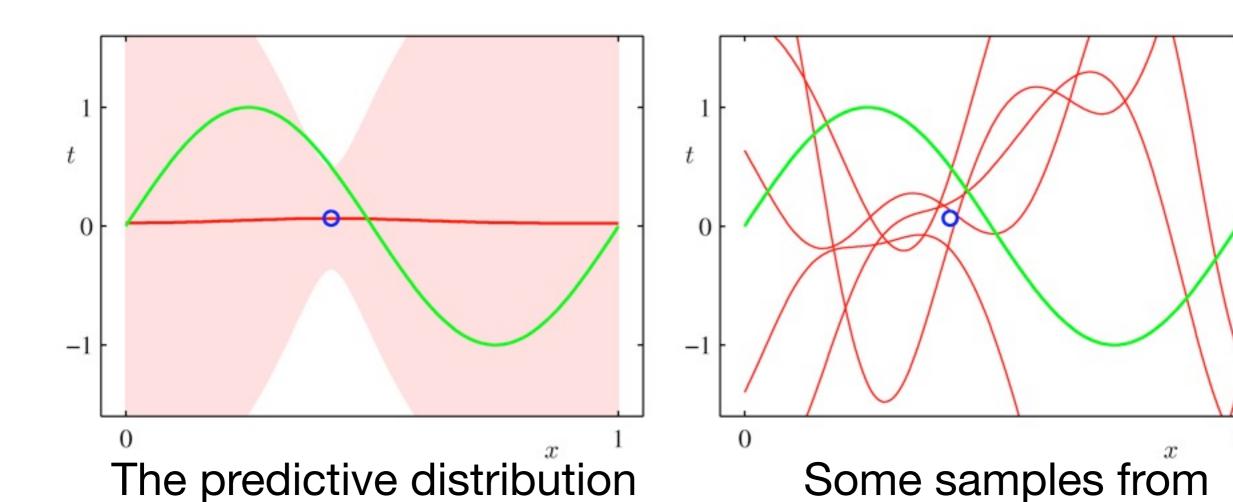

As before the posterior is prop. to the likelihood times the prior. But now, we don't maximize. The posterior can be computed analytically, as the prior is Gaussian.

$$p(\mathbf{w}\mid\mathbf{x},\mathbf{t}) = \mathcal{N}(\mathbf{w}\mid\mathbf{m}_N,S_N) \text{ where } \underbrace{\begin{array}{c} S_N^{-1} = S_0^{-1} + \sigma^{-2}\Phi^T\Phi \\ \text{Prior cov} \end{array}}_{\text{Prior mean}} \underbrace{\begin{array}{c} S_N^{-1} = S_0^{-1} + \sigma^{-2}\Phi^T\Phi \\ \text{Prior mean} \end{array}}_{\text{Prior mean}}$$

the posterior

## **Summary**

- A model that has been found using regression can be evaluated in different ways (e.g. loss function, crossvalidation, leave-one-out, BIC)
- This can be used to adjust model parameters such as , using a validation data set
- Bayesian Linear Regression operates on sequential data and provides the predictive distribution
- When using Gaussian priors (and Gaussian noise), all computations can be done analytically, as all probabilities remain Gaussian
