## 8. Belief Propagation

# Vitr. Overview of the course \*

White

Recall: Inference \*

Inference means the procedure to estimate the probability distribution, encoded by a graphical model, for a given data (or observation).

Assume we are given a factor graph  $G = (\mathcal{V}, \mathcal{E}', \mathcal{F})$  and the observation  $\mathbf{x}$ .

Maximum A Posteriori (MAP) inference: find the state  $y^* \in \mathcal{Y}$  of maximum probability,

$$\mathbf{y}^* \in \operatorname*{argmax}_{\mathbf{y} \in \mathcal{Y}} p(\mathbf{y} \mid \mathbf{x}) = \operatorname*{argmin}_{\mathbf{y} \in \mathcal{Y}} E(\mathbf{y}; \mathbf{x}) \ .$$

**Probabilistic inference**: find the value of the partition function  $Z(\mathbf{x})$  and the marginal distributions  $\mu_F(\mathbf{y}_F)$  for each factor  $F \in \mathcal{F}$ ,

$$\begin{split} Z(\mathbf{x}) &= \sum_{\mathbf{y} \in \mathcal{Y}} \exp(-E(\mathbf{y}; \mathbf{x})) \;, \\ \mu_F(\mathbf{y}_F) &= p(\mathbf{y}_F \mid \mathbf{x}) \;. \end{split}$$

## Agenda for today's lecture \*

Today we are going to learn about belief propagation to perform exact inference on graphical models having tree structure.

Reminder: a tree is a connected and acyclic graph.

- Probabilistic inference: Sum-product algorithm
- MAP inference: Max-sum algorithm

We also extend belief propagation for general factor graphs, which results in an approximate inference.

## Probabilistic inference on chains

Assume that we are given the following factor graph and a corresponding energy function  $E(\mathbf{y})$ , where  $\mathcal{Y} = \mathcal{Y}_i \times \mathcal{Y}_j \times \mathcal{Y}_k \times \mathcal{Y}_l$ .

We want to compute  $p(\mathbf{y})$  for any  $\mathbf{y} \in \mathcal{Y}$  by making use of the factorization

$$p(\mathbf{y}) = \frac{1}{Z} \exp(-E(\mathbf{y})) = \frac{1}{Z} \exp(-E_A(y_i, y_j)) \exp(-E_B(y_j, y_k)) \exp(-E_C(y_k, y_l)).$$

Problem: we also need to calculate the partition function

$$Z = \sum_{\mathbf{y} \in \mathcal{Y}} \exp(-E(\mathbf{y})) = \sum_{y_i \in \mathcal{Y}_i} \sum_{y_j \in \mathcal{Y}_j} \sum_{y_k \in \mathcal{Y}_k} \sum_{y_l \in \mathcal{Y}_l} \exp(-E(y_i, y_j, y_k, y_l)) ,$$

which looks expensive (the sum has  $|\mathcal{Y}_i| \cdot |\mathcal{Y}_i| \cdot |\mathcal{Y}_k| \cdot |\mathcal{Y}_l|$  terms).

#### Partition function

We can expand the partition function as

$$Z = \sum_{y_i \in \mathcal{Y}_i} \sum_{y_j \in \mathcal{Y}_j} \sum_{y_k \in \mathcal{Y}_k} \sum_{y_l \in \mathcal{Y}_l} \exp(-E(y_i, y_j, y_k, y_l))$$

$$= \sum_{y_i \in \mathcal{Y}_i} \sum_{y_j \in \mathcal{Y}_j} \sum_{y_k \in \mathcal{Y}_k} \sum_{y_l \in \mathcal{Y}_l} \exp\left(-\left(E_A(y_i, y_j) + E_B(y_j, y_k) + E_C(y_k, y_l)\right)\right)$$

$$= \sum_{y_i \in \mathcal{Y}_i} \sum_{y_j \in \mathcal{Y}_j} \sum_{y_k \in \mathcal{Y}_k} \sum_{y_l \in \mathcal{Y}_l} \exp(-E_A(y_i, y_j)) \exp(-E_B(y_j, y_k)) \exp(-E_C(y_k, y_l))$$

 $= \sum_{y_i \in \mathcal{Y}_i} \sum_{y_j \in \mathcal{Y}_j} \exp(-E_A(y_i, y_j)) \sum_{y_k \in \mathcal{Y}_k} \exp(-E_B(y_j, y_k)) \sum_{y_l \in \mathcal{Y}_l} \exp(-E_C(y_k, y_l)).$ 

$$Z = \sum_{y_i \in \mathcal{Y}_i} \sum_{y_j \in \mathcal{Y}_j} \exp(-E_A(y_i, y_j)) \sum_{y_k \in \mathcal{Y}_k} \exp(-E_B(y_j, y_k)) \underbrace{\sum_{y_l \in \mathcal{Y}_l} \exp(-E_C(y_k, y_l))}_{y_l \in \mathcal{Y}_l}$$

$$= \sum_{y_i \in \mathcal{Y}_i} \sum_{y_j \in \mathcal{Y}_j} \exp(-E_A(y_i, y_j)) \sum_{y_k \in \mathcal{Y}_k} \exp(-E_B(y_j, y_k)) r_{C \to Y_k}(y_k) \underbrace{r_{B \to Y_j}(y_j)}$$

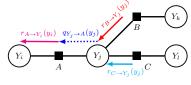

$$r_{B \to Y_j}(y_j)$$

$$= \sum_{y_i \in \mathcal{Y}_i} \underbrace{\sum_{y_j \in \mathcal{Y}_j} \exp(-E_A(y_i, y_j)) r_{B \to Y_j}(y_j)}_{r_{A \to Y_i}(y_i)} = \underbrace{\sum_{y_i \in \mathcal{Y}_i} r_{A \to Y_i}(y_i)}_{r_{A \to Y_i}(y_i)}.$$

Ulin.

## Inference on trees (cont.)

Now we are assuming a tree-structured factor graph and applying the same elimination procedure as before.

$$Z = \sum_{y_i \in \mathcal{Y}_i} \underbrace{\sum_{y_j \in \mathcal{Y}_j} \exp(-E_A(y_i, y_j)) q_{Y_j \to A}(y_j)}_{r_{A \to Y_i}(y_i)}$$
$$= \sum_{y_i \in \mathcal{Y}_i} r_{A \to Y_i}(y_i) .$$

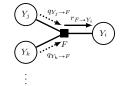

Ville.

## Factor-to-variable message

2. Factor-to-variable message  $r_{F \to Y_i} \in \mathbb{R}^{\mathcal{Y}_i}$  is given by

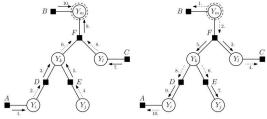

$$r_{F \to Y_i}(y_i) = \sum_{\substack{\mathbf{y}_F' \in \mathcal{Y}_F, \\ y_i = y_i}} \left( \exp(-E_F(\mathbf{y}_F')) \prod_{l \in N(F) \setminus \{i\}} q_{Y_l \to F}(y_l') \right),$$

where  $N(F) = \{i \in V : (i, F) \in \mathcal{E}'\}$  denotes the set of variables adjacent to F.

#### Message scheduling on trees

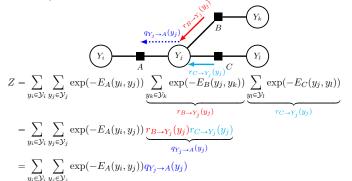

For tree-structured factor graphs there always exist at least one such message that can be computed initially, hence all the dependencies can be resolved.

- Select one variable node as root of the tree (e.g.,  $Y_m$ ) Compute leaf-to-root messages (e.g., by applying depth-first-search)
- Compute root-to-leaf messages (reverse order as before)

#### Inference on trees

Now we are assuming a tree-structured factor graph and are applying the same elimination procedure as before.

#### Thir. Messages

**Message**: pair of vectors at each factor graph edge  $(i, F) \in \mathcal{E}'$ .

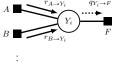

1. Variable-to-factor message  $q_{Y_i \to F} \in \mathbb{R}^{\mathcal{Y}_i}$  is

$$q_{Y_i \to F}(y_i) = \prod_{F' \in M(i) \setminus \{F\}} r_{F' \to Y_i}(y_i) ,$$

where  $M(i) = \{ F \in \mathcal{F} : (i, F) \in \mathcal{E}' \}$  denotes the set of factors adjacent to  $Y_i$ .

Factor-to-variable message:  $r_{F \to Y_i} \in \mathbb{R}^{\mathcal{Y}_i}$ 

## Message scheduling \*

Tible.

One can note that the message updates depend on each other.

$$r_{F \to Y_i}(y_i) = \sum_{\substack{\mathbf{y}_F' \in \mathcal{Y}_F, \\ y_i' = y_i}} \left( \exp(-E_F(\mathbf{y}_F')) \prod_{l \in N(F) \setminus \{i\}} q_{Y_l \to F}(y_l') \right) \tag{1}$$

$$q_{Y_i \to F}(y_i) = \prod_{F' \in M(i) \setminus \{F\}} r_{F' \to Y_i}(y_i) \tag{2}$$

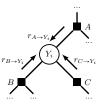

The messages that do not depend on previous computation are the following.

- The factor-to-variable messages in which no other variable is adjacent to the factor, that is the product in (1) will be empty.
- The variable-to-factor messages in which no other factor is adjacent to the variable, that is the product in (2) is empty and the message will be one.

# Inference result: partition function Z

Partition function is evaluated at the (root) node i

$$Z = \sum_{y_i \in \mathcal{Y}_i} \prod_{F \in M(i)} r_{F \to Y_i}(y_i) .$$

## Inference result: the marginals $\mu_F(\mathbf{y}_F)$

The marginal distribution for each factor can be computed as

$$\mu_{F}(\mathbf{y}_{F}) \stackrel{\Delta}{=} \sum_{\substack{\mathbf{y}' \in \mathcal{Y}, \\ \mathbf{y}_{F} = \mathbf{y}_{F}}} p(\mathbf{y}) = \sum_{\substack{\mathbf{y}' \in \mathcal{Y}, \\ \mathbf{y}_{F} = \mathbf{y}_{F}}} \frac{1}{Z} \exp(-\sum_{H \in \mathcal{F}} E_{H}(\mathbf{y}'_{H}))$$

$$= \frac{1}{Z} \exp(-E_{F}(\mathbf{y}_{F})) \sum_{\substack{\mathbf{y}' \in \times \\ H \in \mathcal{F} \setminus \{F\}}} \exp(\sum_{H \in \mathcal{F} \setminus \{F\}} -E_{H}(\mathbf{y}'_{H}))$$

$$= \frac{1}{Z} \exp(-E_{F}(\mathbf{y}_{F})) \prod_{i \in N(F)} q_{Y_{i} \to F}(y_{i}) .$$

$$q_{Y_{i} \to F} \stackrel{\mathbf{y}_{F}}{\longrightarrow} q_{Y_{i} \to F} \stackrel{\mathbf{y}_{F}$$

#### Optimality and complexity \*

Assume a tree-structured factor graph. If the messages are computed based on depth-first search order for the sum-product algorithm, then it converges after  $2|\mathcal{V}|$ iterations and provides the exact marginals.

If  $|\mathcal{Y}_i| \leq K$  for all  $i \in \mathcal{V}$ , then the complexity of the algorithm  $\mathcal{O}(|\mathcal{V}| \cdot K^L)$ , where  $L = \max_{F \in F} |N(F)|$ .

$$r_{F \to Y_i}(y_i) = \sum_{\substack{\mathbf{y}_F' \in \mathcal{Y}_F, \\ y_i' = y_i}} \left( \exp(-E_F(\mathbf{y}_F')) \prod_{j \in N(F) \setminus \{i\}} q_{Y_j \to F}(y_j') \right).$$

Note that the complexity of the naïve way is  $\mathcal{O}(K^{|\mathcal{V}|})$ .

Reminder. Assuming  $f, g : \mathbb{R} \to \mathbb{R}$ , the notation  $f(x) = \mathcal{O}(g(x))$  means that there exists C>0 and  $x_0\in\mathbb{R}$  such that  $|f(x)|\leqslant C|g(x)|$  for all  $x>x_0$ .

Max-sum algorithm

## THE P

#### **MAP** inference

$$\mathbf{y}^* \in \operatorname*{argmax}_{\mathbf{y} \in \mathcal{Y}} p(\mathbf{y}) = \operatorname*{argmax}_{\mathbf{y} \in \mathcal{Y}} \frac{1}{Z} \tilde{p}(\mathbf{y}) = \operatorname*{argmax}_{\mathbf{y} \in \mathcal{Y}} \tilde{p}(\mathbf{y}) \; .$$

Similar to the sum-product algorithm one can obtain the so-called max-sum algorithm to solve the above maximization.

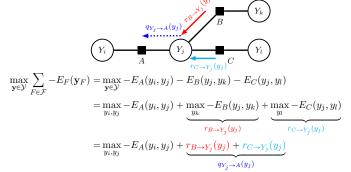

By applying the  $\ln$  function, we have

$$\begin{split} \ln \max_{\mathbf{y} \in \mathcal{Y}} \tilde{p}(\mathbf{y}) &= \max_{\mathbf{y} \in \mathcal{Y}} \ln \tilde{p}(\mathbf{y}) \\ &= \max_{\mathbf{y} \in \mathcal{Y}} \ln \prod_{F \in \mathcal{F}} \exp(-E_F(\mathbf{y}_F)) \\ &= \max_{\mathbf{y} \in \mathcal{Y}} \sum_{F \in \mathcal{F}} -E_F(\mathbf{y}_F) \; . \end{split}$$

# White.

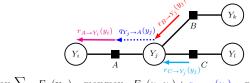

#### MAP inference on trees

Now we are assuming a tree-structured factor graph and applying an elimination procedure as before.

#### MAP inference on trees (cont.)

Now we are assuming a tree-structured factor graph and applying an elimination procedure as before.

$$\max_{\mathbf{y} \in \mathcal{Y}} \sum_{F \in \mathcal{F}} -E_F(\mathbf{y}_F) = \max_{y_i} \underbrace{\max_{y_j} -E_A(y_i, y_j) + q_{Y_j \to A}(y_j)}_{r_{A \to Y_i}(y_i)} = \max_{y_i} r_{A \to Y_i}(y_i)$$

The solution is then obtained as:  $y_i^* \in \operatorname{argmax} r_{A \to Y_i}(y_i),$ 

$$y_i^r \in \operatorname{argmax} r_{A \to Y_i}(y_i),$$

$$y_j^* \in \underset{y_j}{\operatorname{argmax}} -E_A(y_i^*, y_j) + q_{Y_j \to A}(y_j),$$

$$y_k^* \in \operatorname{argmax} -E_B(y_j^*, y_k),$$

$$y_l^* \in \operatorname{argmax} -E_C(y_j^*, y_l)$$
.

#### Messages

Max-sum algorithm

The messages become as follows

$$\begin{split} q_{Y_i \to F}(y_i) &= \sum_{F' \in M(i) \backslash \{F\}} r_{F' \to Y_i}(y_i) \\ r_{F \to Y_i}(y_i) &= \max_{y_F' \in \mathcal{Y}_F,} \left( -E_F(y_F') + \sum_{l \in N(F) \backslash \{i\}} q_{Y_l \to F}(y_l') \right). \end{split}$$

The max-sum algorithm provides exact MAP inference for tree-structured factor graphs.

#### Choosing an optimal state

Sum-product algorithm Max-sum algorithm

After calculating the messages, the following back-tracking algorithm is applied for choosing an optimal  $y^*$ 

1. Initialize the procedure at the root node  $(Y_i)$  by choosing any

$$y_i^* \in \underset{y_i \in \mathcal{Y}_i}{\operatorname{argmax}} \underset{\mathbf{y}' \in \mathcal{Y}, y_i' = y_i}{\operatorname{max}} \tilde{p}(\mathbf{y}') ,$$

and set  $\mathcal{I} = \{i\}$ .

- Based on (reverse) depth-first search order, for each  $j \in V \setminus \mathcal{I}$ 
  - (a) choose a configuration  $y_i^*$  at the node  $Y_j$  such that

$$y_j^* \in \underset{y_j \in \mathcal{Y}_j}{\operatorname{argmax}} \max_{\substack{\mathbf{y}' \in \mathcal{Y}, \\ y_j' = y_j, \\ y' = y^* \ \forall i \in \mathcal{T}}} \tilde{p}(\mathbf{y}') ,$$

(b) update  $\mathcal{I} = \mathcal{I} \cup \{j\}$ .

Sum-product algorithm

$$\begin{split} q_{Y_i \to F}(y_i) &= \prod_{F' \in M(i) \backslash \{F\}} r_{F' \to Y_i}(y_i) \\ r_{F \to Y_i}(y_i) &= \sum_{\substack{y_F' \in \mathcal{Y}_F, \\ y_i' = y_i}} \left( \exp(-E_F(y_F')) \prod_{l \in N(F) \backslash \{i\}} q_{Y_l \to F}(y_l') \right) \end{split}$$

Max-sum algorithm

$$\begin{split} q_{Y_i \to F}(y_i) &= \sum_{F' \in M(i) \backslash \{F\}} r_{F' \to Y_i}(y_i) \\ r_{F \to Y_i}(y_i) &= \max_{\substack{y_F' \in \mathcal{Y}_F, \\ y_i' = y_i}} \left( -E_F(y_F') + \sum_{l \in N(F) \backslash \{i\}} q_{Y_l \to F}(y_l') \right) \end{split}$$

## Let us consider the following factor graph with binary variables:

$y_j, y_k)$	$E_B(y_k)$				
$y_k$			$y_k$		
0 1		0	1		
0 -1		1	0.5		
0 0					

0 0 5

Let us chose the node  $Y_i$  as root. We calculate the messages for the  $\emph{max-sum}$ algorithm from leaf-to-root direction in a depth-first search order as follows.

Example

- $q_{Y_l\to C}(0)=q_{Y_l\to C}(1)=0$
- $r_{C \to Y_k}(0) = \max_{y_l \in \{0,1\}} \{-E_C(0,y_l) + q_{Y_l \to C}(0)\} = \max_{y_l \in \{0,1\}} -E_C(0,y_l) = 0$  $r_{C \to Y_k}(1) = \max_{y_l \in \{0,1\}} \{-E_C(1, y_l) + q_{Y_l \to C}(1)\} = \max_{y_l \in \{0,1\}} -E_C(1, y_l) = 0$
- $r_{B \to Y_k}(0) = -1$  $r_{B \to Y_k}(1) = -0.5$
- $q_{Y_k \to A}(0) = r_{B \to Y_k}(0) + r_{C \to Y_k}(0) = -1 + 0 = -1$  $q_{Y_k \to A}(1) = r_{B \to Y_k}(1) + r_{C \to Y_k}(1) = -0.5 + 0 = -0.5$

## Example (cont.) \*

- 5.  $q_{Y_j \to A}(0) = q_{Y_j \to A}(1) = 0$
- $r_{A \to Y_i}(0) = \max_{y_j, y_k \in \{0,1\}} \left\{ -E_A(0, y_j, y_k) + q_{Y_j \to A}(y_j) + q_{Y_k \to A}(y_k) \right\} = -0.5$  $r_{A \to Y_i}(1) = \max_{y_i, y_k \in \{0, 1\}} \{ -E_A(1, y_i, y_k) + q_{Y_j \to A}(y_j) + q_{Y_k \to A}(y_k) \} = 0.5$

In order to calculate the maximal state  $y^*$  we apply back-tracking

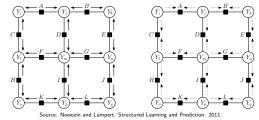

- $y_i^* \in \operatorname{argmax}_{y_i \in \{0,1\}} r_{A \to Y_i}(y_i) = \{1\}$
- 2.  $y_i^* \in \operatorname{argmax}_{y_i} \max_{y_i, y_k \in \{0,1\}} \{-E_A(1, y_j, y_k) + q_{Y_k \to A}(y_k)\} = \{0\}$
- 3.  $y_k^* \in \operatorname{argmax}_{y_k \in \{0,1\}} \{ -E_A(1,0,y_k) + r_{B \to Y_k}(y_k) + r_{C \to Y_k}(y_k) \} = \{1\}$
- 4.  $y_l^* \in \operatorname{argmax}_{y_l \in \{0,1\}} \{-E_C(1, y_l) + r_{C \to Y_k}(1)\} = \{1\}$

Therefore, the optimal state  $y^*=(y_i^*,y_i^*,y_k^*,y_l^*)=(1,0,1,1)$ 

## Vite.

#### Message passing in cyclic graphs

When the graph has cycles, then there is no well-defined leaf-to-root order. However, one can apply message passing on cyclic graphs, which results in loopy belief propagation.

- Initialize all messages as constant 1
- Pass factor-to-variables and variables-to-factor messages alternately until
- Upon convergence, treat beliefs  $\mu_F$  as approximate marginals

The approximate marginals, i.e.beliefs, are computed as before, but now a factor-specific normalization constant  $z_F$  is also used.

The factor marginals are given by

$$\mu_F(y_F) = \frac{1}{z_F} \exp(-E_F(y_F)) \prod_{i \in N(F)} q_{Y_i \to F}(y_i) ,$$

where the factor specific normalization constant is given by

$$z_F = \sum_{y_F \in \mathcal{Y}_F} \exp(-E_F(y_F)) \prod_{i \in N(F)} q_{Y_i \to F}(y_i) \;.$$

# Loopy belief propagation

# White.

Messages

The factor-to-variable messages  $r_{F \rightarrow Y_i}$  remain well-defined and are computed

$$r_{F \to Y_i}(y_i) = \sum_{\mathbf{y}_F' \in \mathcal{Y}_F,} \left( \exp(-E_F(\mathbf{y}_F')) \prod_{j \in N(F) \setminus \{i\}} q_{Y_j \to F}(y_j') \right).$$

The variable-to-factor messages are simply normalized at every iteration as follows:

$$q_{Y_i \to F}(y_i) = \frac{\prod_{F' \in M(i) \setminus \{F\}} r_{F' \to Y_i}(y_i)}{\sum_{y_i' \in \mathcal{Y}_i} \prod_{F' \in M(i) \setminus \{F\}} r_{F' \to Y_i}(y_i')}$$

Beliefs (cont.) \*

In addition to the factor marginals the algorithm also computes the variable marginals in a similar fashion

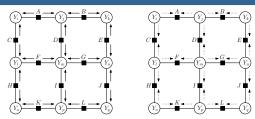

$$\mu_i(y_i) = \frac{1}{z_i} \prod_{F' \in M(i)} r_{F' \to Y_i}(y_i) ,$$

where the normalizing constant is given by

$$z_i = \sum_{y_i \in \mathcal{Y}_i} \prod_{F' \in M(i)} r_{F' \to Y_i}(y_i) .$$

Since the local normalization constant  $z_F$  differs at each factor for loopy belief propagation, the exact value of the normalizing constant Z cannot be directly calculated. Instead, an approximation to the partition function can be computed.

Loopy belief propagation is very popular, but has some problems:

- It might not converge (e.g., it can oscillate).
- Even if it does, the computed probabilities are only approximate.
- If there is a single cycle only in the graph, then it converges.
