### Binary Matching

### 2D Shape

Binary Matching

Simultaneous Matching

Semi-Metric Mean

If a 2D shape  $S$  stems from a 2D object  $O$  with a connected 1D-boundary, we usually represent it by two different functions

$$c: \mathbb{S}^1 \rightarrow \mathbb{R}^2 \quad f: \mathbb{S}^1 \rightarrow \mathbb{R}^k,$$

where

- $c$  describes a **specific parametrization** of the boundary of a **specific object**  $O$  corresponding to the shape  $S$ .
- $f$  describes the **shape features**, which help to describe the shape  $S$  and not the object  $O$ .

### Matching of Two 2D Shapes

Binary Matching

Simultaneous Matching

Semi-Metric Mean

Given two shapes  $S_1$  and  $S_2$  with their representations  $c_1, c_2: \mathbb{S}^1 \rightarrow \mathbb{R}^2$  as well as  $f_1, f_2: \mathbb{S}^1 \rightarrow \mathbb{R}^k$ , we define the matching energy for an arbitrary matching function  $m: \mathbb{S}^1 \rightarrow \mathbb{S}^1$  as

$$E_{S_1, S_2}(m) = \int_{\mathbb{S}^1} \text{dist}_{\mathcal{F}}(f_1(t), f_2 \circ m(t)) \cdot \sqrt{\dot{c}_1(t)^2 + \frac{d}{dt}(c_2 \circ m)(t)^2} dt.$$

This leads to a semi-metric  $\text{dist}(\cdot, \cdot)$  of shapes

$$\text{dist}(S_1, S_2) = \min_{m \in \text{Diff}(\mathbb{S}^1)} E_{S_1, S_2}(m),$$

where  $\text{Diff}(\mathbb{S}^1)$  describes the set of diffeomorphic mappings  $m: \mathbb{S}^1 \rightarrow \mathbb{S}^1$ .

### Classification Task

Binary Matching

Simultaneous Matching

Semi-Metric Mean

A common task in computer vision is known as **classification**. Here, we assume a set  $\mathcal{O}$  of possible **observations**, a smaller class  $\mathcal{C}$  of different **classes** and a **classifier**

$$\Phi: \mathcal{O} \rightarrow \mathcal{C}$$

that assign to each observation its unique class.

In general, neither  $\mathcal{O}$  nor  $\Phi$  are known. The goal of classification is to estimate  $\Phi$  by providing a certain amount of classified observations.

$(S_i, \ell_i)_{i \in \mathcal{I}}$  contains observations  $S_i \in \mathcal{O} \subset \mathbb{R}^N$  and class labels  $\ell_i \in \mathcal{C}$ . Estimating  $\Phi$  can be formulated as finding a function  $\hat{\Phi}: \mathbb{R}^N \rightarrow \mathcal{C}$  such that  $\hat{\Phi}(S_i) = \ell_i$ . Estimating  $\Phi$  based on certain observations is called **training**.

Most of the known classification methods use the canonical metric on  $\mathbb{R}^N$  in order to **train the classifier**.

### Classification of Shapes

Binary Matching

Simultaneous Matching

Semi-Metric Mean

If we want to classify shapes, we have more information about the observation space, i.e., **shape space**. Instead of using the metric of some embedding space, we can directly use the **semi-metric** of the shape space.

In fact, it is common to use a simplified classifier framework in order to evaluate shape distances. Given a shape dataset  $\mathcal{S}$ , one computes in a first step for each pair  $(S_i, S_j) \in \mathcal{S}^2$  their shape distance.

In a second step, we **retrieve** for each shape  $S_i$  its  $k$  nearest neighbors  $S_i^k$ , i.e., the  $k$  shapes of a given dataset that have the smallest distance with respect to  $S_i$ .

Evaluating how well these  $k$  nearest neighbors coincide with the perceptual shape class gives us a measure on how well the shape distance measures the practical shape similarity that we like to model.

### MPEG-7 CE Shape-1 Part-B

Binary Matching

Simultaneous Matching

Semi-Metric Mean

**MPEG-7** is a standard to describe multimedia content. In contrast to MPEG-1, MPEG-2 and MPEG-4 it does not introduce a new encoding scheme. Instead it provides meta-information.

One of the **core experiments** was with respect to shape. The **CE Shape-1** contains 4 different databases. From particular interest is **Part-B**.

This database contains 70 shape classes with 20 objects contained in each class. This provides us with a very big database of 1400 shapes. Computing all pairwise distances results in about **2 million** shape matching tasks.

The **bull's eye test** with respect to the MPEG7 shape database asks for the computation of the 40 nearest neighbors. The **recall** of a specific shape is the ratio of correctly retrieved shapes and 20. The **bull's eye score** is the average recall for all 1400 objects. At this point, every method achieved a score below 90%.

## Simultaneous Matching

## Lack of Knowledge

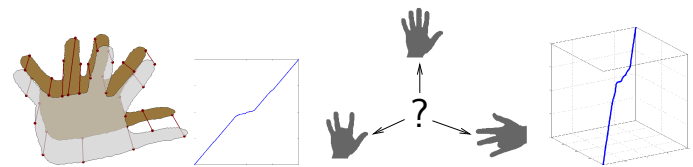

If we compare two objects of the same shape class, we might miss some vital information of the whole shape class.

For that reason, we would expect a better shape matching if we consider multiple shapes at the same time in order to obtain more information.

This leads us to the problem of **simultaneous shape matching**.

## Outline

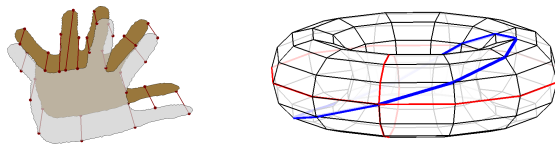

Given two shapes (discretized by  $N$  points each) and an initial match, we can compute the optimal matching in  $\mathcal{O}(N^2)$ .

We want to extend this idea to multiple shapes. This can be cast as finding a shortest path in a higher-dimensional graph.

After finding such a matching path, we like to use it in order to define a **mean shape** of multiple shapes.

## Simultaneous Shape Matching

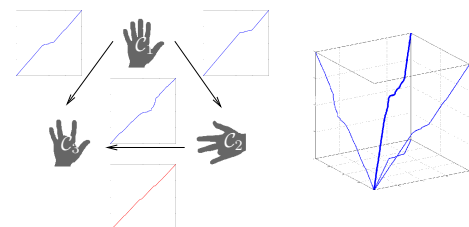

For  $d$  different shapes, the optimal matching  $m = (m_1, \dots, m_d) : \mathbb{S}^1 \rightarrow (\mathbb{S}^1)^d$  shall minimize the energy functional:

$$E(m) := \sum_{i,j=1}^d E_{S_i, S_j}(m_{ij}), \quad m_{ij} = m_j \circ m_i^{-1}$$

and can be represented as a loop on the  $d$ -dimensional torus  $\mathbb{S}^1 \times \dots \times \mathbb{S}^1$ .

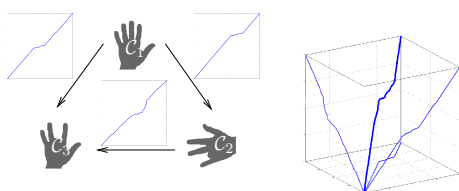

## Relationship to 2-Matching

Given an initial match of all  $d$  shapes, the whole matching can be described by a shortest path in a  $d$ -dimensional cube.

Projecting the path on the cube's 2D faces, results in  $\binom{d}{2}$  2-matchings.

These 2-matching are more consistent than independent pairwise matchings.

Running Time of  $d$ -Matching

Given an initial match of  $d$  shapes (discretized by  $N$  nodes each), results in a graph of  $N^d$  nodes and a running time for the optimal path of  $\mathcal{O}(N^d)$ .

Testing also all  $N^{d-1}$  initial matches leads us to a running time of  $\mathcal{O}(N^{2d+1})$ .

We were only able to reduce this running time for  $d = 2$ , because the resulting graph is planar and we can apply a binary search of the graph's domain.

## Approximating Energy

Instead of minimizing

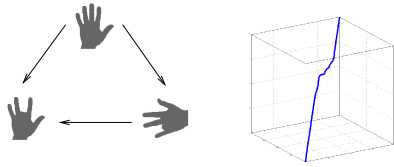

$$E(m_1, \dots, m_d) = \sum_{i,j=1}^d \underbrace{E_{S_i, S_j}(m_{ij})}_{\text{pairwise matching}} \quad m_{ij} := m_j \circ m_i^{-1}$$

we would like to minimize the following energy

$$\hat{E}(m_{11}, \dots, m_{dd}) = \sum_{i,j=1}^d \left[ \underbrace{E_{S_i, S_j}(m_{ij})}_{\text{pairwise matching}} + \gamma \cdot \int_{\Gamma(m_{ij})} \sum_{k=1}^d \underbrace{\|(m_{ij} - m_{kj} \circ m_{ik})(s)\|}_{\text{consistency costs}} ds \right]$$

# Minimizing the Approximative Energy

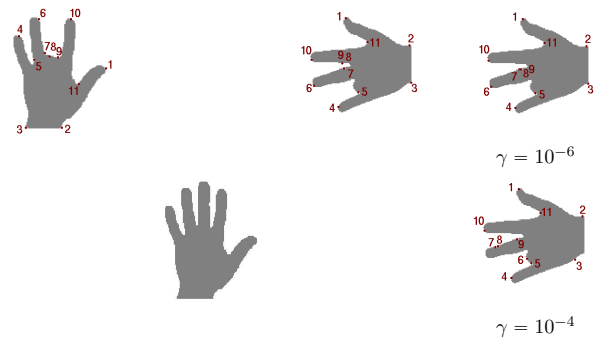

Binary Matching Simultaneous Matching Semi-Metrical Mean

1. Start with the 2-matchings  $m_{ij}$  that minimize  $E_{S_i, S_j}$ .
  2. Minimize the functional  $\tilde{E}(\cdot)$  with respect to  $m_{ij}$  for each  $m_{ij}$  until convergence.
- Instead of  $\mathcal{O}(N^d)$  graph nodes, we need only  $\mathcal{O}(d^2 \cdot N^2)$ .
  - Instead of  $\mathcal{O}(N^{2d-1})$  steps, every iteration needs only  $\mathcal{O}(d^2 \cdot N^2 \log(N))$ .

# Results of the Approximation

Binary Matching Simultaneous Matching Semi-Metrical Mean

## Semi-Metrical Mean

Binary Matching Simultaneous Matching Semi-Metrical Mean

If we take  $n$  samples  $x_1, \dots, x_n \in \mathbb{R}^n$  of an  $n$ -dimensional vector space, the mean is usually defined as

$$\mu = \frac{1}{n} \sum_{i=1}^n x_i$$

Interestingly, it is equivalent to the following formulation

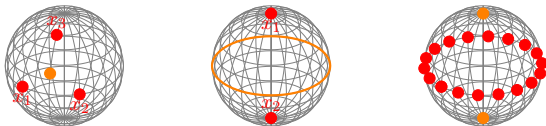

$$\mu = \operatorname{argmin}_{x^* \in \mathbb{R}^n} \sum_{i=1}^n \|x_i - x^*\|^2$$

Thus, we can define a mean  $\mu$  of  $n$  samples  $x_1, \dots, x_n \in X$  of a metrical or even semi-metrical space  $X$  as

$$\mu = \operatorname{argmin}_{x^* \in X} \sum_{i=1}^n \operatorname{dist}(x_i, x^*)^2$$

## Karcher Mean

Binary Matching Simultaneous Matching Semi-Metrical Mean

Karcher was the first who introduced this mean for manifolds. Note that a manifold  $M$  becomes a metric via

$$\operatorname{dist}(x, y) = \min_{\substack{c: [0,1] \rightarrow M, \\ c(0)=x, c(1)=y}} \operatorname{length}(c)$$

The Karcher mean is well-defined if the samples are close to one another.

For samples that are widely spread on a manifold, there might be multiple Karcher means that minimize the involved energy function.

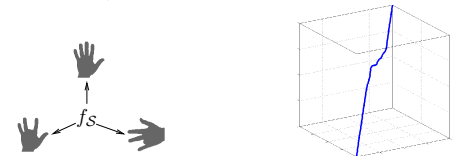

## Matching-Driven Mean

Binary Matching Simultaneous Matching Semi-Metrical Mean

We like to define the mean of a collection  $\mathcal{S} = \{S_1, \dots, S_d\}$  of shapes with respect to the (approximative) simultaneous shape matching functions  $(m_{ij})_{i,j=1, \dots, d}$

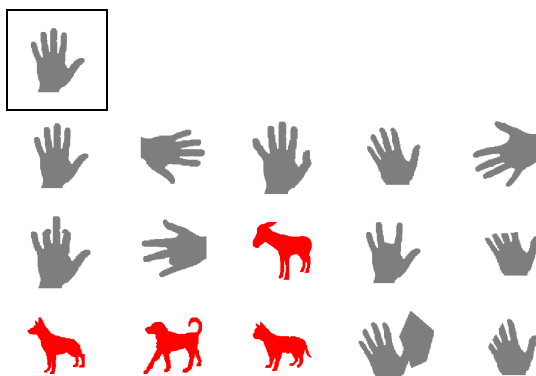

The feature representation  $f_S$  of this collection shall minimize the energy

$$f^* \mapsto \sum_{i=1}^d \int_{\Gamma(m_{1i})} \operatorname{dist}_{\mathcal{F}}(f^*(s_1), f_i(s_2))^2 \, ds.$$
